Anatomy of the word ‘shellacking’

By GLENN TOWNES Special to the AmNews

It’s quite possible that someone infected with the HIV virus will live just as long as someone without the virus, according to a study released last month in the United Kingdom.

According to the UK Collaborative HIV Cohort study released in November, HIV-positive individuals who maintain an antiretroviral (ARV) regimen; have a low viral load and have a CD4 count of 350 or more; and are not co-infected with hepatitis may have normal life expectancies.

The findings were unveiled at a conference in Glasgow, Scotland. Scientists contend the findings are indicative of the advancements made in the treatment of HIV/AIDS and the effectiveness of antiretroviral drugs.

Additionally, maintaining a significantly higher CD4 count also increases life expectancy. For example, a 35-year-old male with a CD4 count of between 350-500 and on a solid drug cocktail regimen could live to the age of 77 or longer, the study showed.

“I’ve been living with HIV since 1991,” said Robert, a 51-year-old African-American from the Midwest. “I worry more about being the victim of a crime or hit by a car than I do about dying from HIV/AIDS.”
